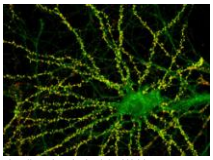
Neurotransmitters in the Brain: from rapid information transfer to long term synaptic plasticity



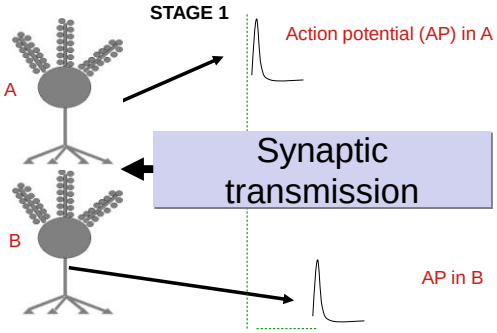
http://www.its.caltech.edu/~mbklab/

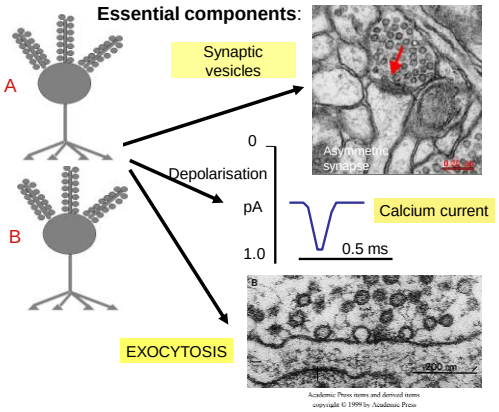
Molecular basis of memory

Synaptic transmission

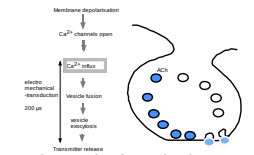
1. Transmitter released from 1st cell
2. Synaptic activation of 2nd cell
3. Signal integration and signal conduction by 2nd cell
4. Pathway activation

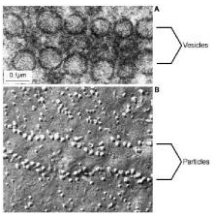
Rapid timescale
Diversity
Adaptability
Plasticity
Learning and memory





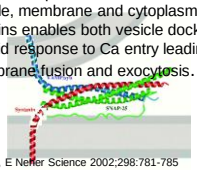
Transmitter release requires Ca^{2+} and requires RAPID transduction

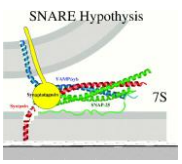




Heuser and Reece 1973

Protein complex formation between vesicle, membrane and cytoplasmic proteins enables both vesicle docking and a rapid response to Ca entry leading to membrane fusion and exocytosis.





J Rettig, E Neher Science 2002;298:781-785

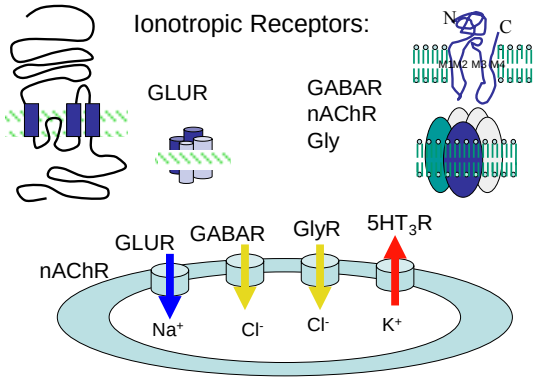
STAGE 2

NEUROTRANSMITTERS

- Provide enormous diversity in variety of transmitters and their receptors.
- **Amino acids** (e.g. glutamate, gamma amino butyric acid [GABA], glycine [gly]), **amines** (e.g. noradrenaline [NA] and dopamine [DA]) and **neuropeptides** (e.g. opioid peptides).
- May mediate rapid (µs - ms) or slower effects (ms)
- Vary in abundance from mM to nM in CNS tissue
- Neurones receive multiple transmitter influences which are integrated to produce diverse responses

Neurotransmitter action is defined by receptor kinetics

Ion channel receptor	G-protein-coupled receptor
	Mediate all fast excitatory and inhibitory transmission	Effectors may be enzymes (adenyl cyclase, phospholipase C, cGMP-PDE) or channels (e.g. Ca^{2+} or K^+)
Glutamate, gamma amino butyric acid (GABA), glycine nicotinic receptors	muscarinic receptors, dopamine (DA), noradrenaline (NA), 5-hydroxytryptamine (5HT) and neuropeptides



$GABA_A$ receptors mediate most fast INHIBITORY responses

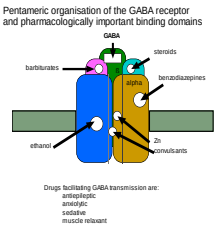
- Activate chloride ion conductance
- Somatic location - profound effect
- Subunits encoded by 17 genes: α (6), β(4), γ(4), delta(1) and rho(2) subtypes
- Each subunit contributes a unique property and exhibits a distinct pattern of distribution: α1 is most abundant, α3 forebrain, α6 cerebellum

The most common native receptor contains α1, β2 and γ2

$GABA_A$ receptor subunits possess different properties

- GABA affinity (μM to mM) defined by the α subunit
- Each subunit confers a different response to BZ, Barbiturates, ethanol, steroids

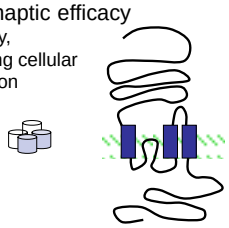
- BZ modulation requires β1
- Ethanol modulation most evident in: α6 β2 $\gamma 2_L$ receptors which are localised in cerebellum (motor incoordination)



GLUTAMATE RECEPTORS

- Excitatory transmission in primarily mediated by Ionotropic glutamate receptors (iGLURs)
- iGLURs mediate basic information processing and underlie changes in synaptic efficacy
  - e.g. learning and memory, developing and maintaining cellular connections,pain perception

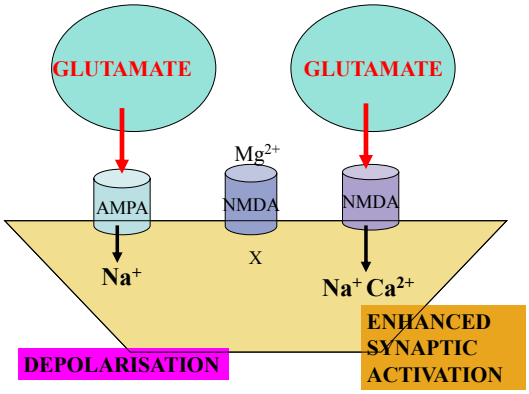
Receptors are composed of 4 subunits, each with 3 TMs and a loop



There are 3 main glutamate receptors, each having a unique role

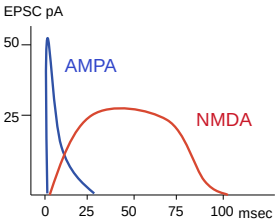
AMPA - main receptor mediating fast CNS transmission (GluR1,2,3,4)
NMDA - coincidence detection and synaptic adaptation (NR1, NR2A, B, C, D, NR3)
Kainate - modulatory role at pre and post synaptic sites (GluR5,6,7, KA1,2). Agonists are potent convulsants and environmental neurotoxins.

AMPA = (S)- -Amino-3-hydroxy-5-methyl-4-isoxazole propionic acid,
NMDA = N-methyl-D-aspartate



AMPA

Fast gating kinetics
Desensitise strongly
Poorly permeable to Ca^{2+} typically
Blocked by polyamines



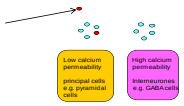
NMDA

Gate much more slowly
Desensitise weakly
Highly calcium permeable
Blocked by extracellular Mg^{2+} in a strongly voltage dependent manner

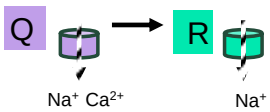
The native **AMPA** receptor is a tetrameric (dimer of dimers) complex formed from GLUR1, GLUR2, GLUR3 and GLUR4

- Most receptors contain GLUR2 which confers Ca^{2+} impermeability *(typical of AMPA receptors in vivo)*
- Expression of GLUR2 with either GLUR1 or GLUR3 yields a receptor with little divalent Ca^{2+} permeability *(Equivalent to AMPA receptor response in situ in pyramidal cells).*
- Expression of GLUR1 or GLUR3 alone or in combination yields a Ca^{2+} permeable channel *(unlike the native receptor !)*

GLUR2 has functional dominance



RNA EDITING



In GluR2 there is a glutamine residue (Q) present in the primary genomic sequence which is edited to arginine R. This confers the change in property from calcium permeable to calcium impermeable.
GluR2 editing is ~100% in adult mammalian brain

Editing requires:
•formation of double stranded RNA around the critical region with adjacent pairing in the intronic region
•Double stranded RNA adenosine deaminase (CAG to CIG)

GluR2 determines calcium permeability

Q/R

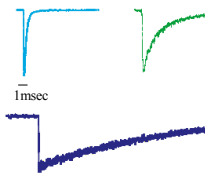
Q/R editing is essential in the adult for mediating physiological excitation

Transgenic mice in which the GluR2 editing site has been mutated
↓
Calcium permeability increased
↓
Severe epileptic seizures
↓
Cell death in hippocampus
↓
Mice die at 3 weeks

Rapid excitatory transmission: NMDA receptors

- Strong afferent stimulation is needed to produce sufficient depolarisation to remove the Mg^{2+} block and activate N-methyl-D-aspartate receptors causing Ca^{2+} and Na^{+} influx.
- NMDA receptors are critical for the induction of certain forms of synaptic plasticity
- Receptors associate with other signalling molecules e.g. kinases to mediate their postsynaptic response.

NMDA receptors (NR1 + NR2A-D/NR3)



Receptors with NR2B subunits instead of NR2A stay open longer - functional consequences?

NR2B-receptors have a longer phase of memory activation increasing the window during which coincidence detection can occur. Animals with increased expression of the NR2B subunit have an enhanced ability to learn (see later).

The modulatory NR2 subunits have profound effects on receptor kinetics

Cull-Candy & Leszkiewicz (2004)

Ionotropic Glutamate receptors are formed from subunits which are encoded by 18 genes which gives structural DIVERSITY

- due to multiple subunit combinations
- RNA editing
- multiple splice variants
- post-translational modifications

which translates into functional DIVERSITY

- ion channel properties
- regional specificity
- developmental specificity
- adaptation to synaptic activity

STAGE 3 Integration of Signals

The NMDA synapse provides a "molecular model of associative memory"

If two neurones are excited at the same time then the active synapse between them is strengthened (Hebb's rule).

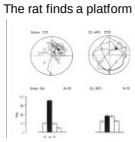
COINCIDENCE DETECTION

- A change in the efficiency of synaptic transmission ("Long term potentiation"- **LTP**.)
- Occurs during development, learning new skills, responding to environmental changes (harmless/noxious)
- Long lasting effects require protein synthesis

The hippocampus is a major site of learning: consolidation of new long term memory

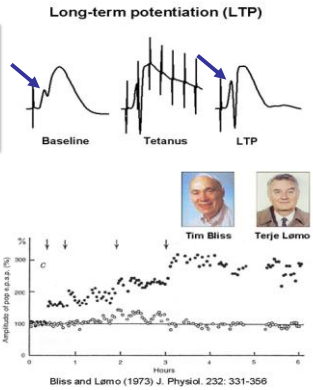
Morris water maze

The rat finds a platform



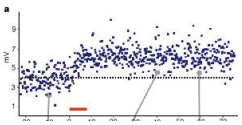
- Spatial navigation learning in rats depends on a hippocampal "map of spatial relations"
- NMDA R antagonists impair learning
- Several forms of ASSOCIATIVE memory are mediated by GLUTAMATE at the NMDA receptor and these are widely used models
- Effects are long lasting and depend on protein synthesis.

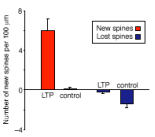
Evoked potentials in the hippocampus



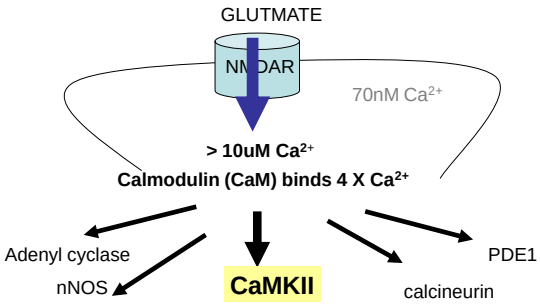
NMDA receptor-mediated Long Term Potentiation in the hippocampus provides a model of learning

Dendritic spine changes associated with hippocampal long-term synaptic plasticity
Florian Engert & Tobias Bonhoeffer

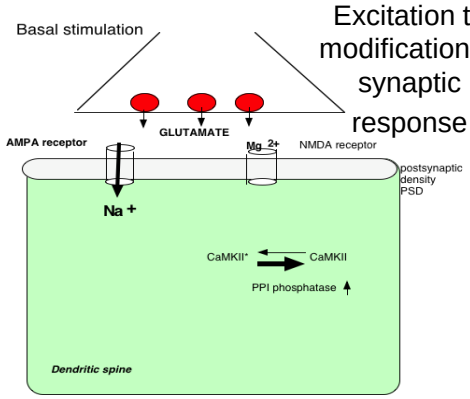




NMDA receptor and calcium signalling
calcium triggers multiple signals



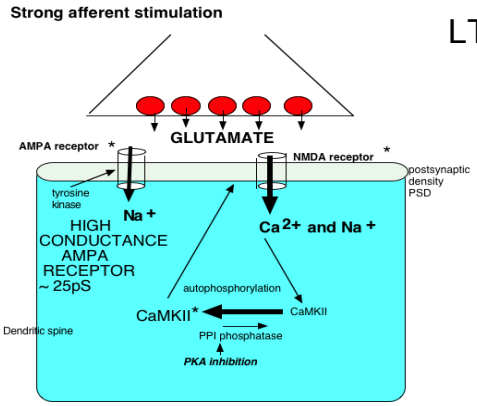
Excitation to modification of synaptic response



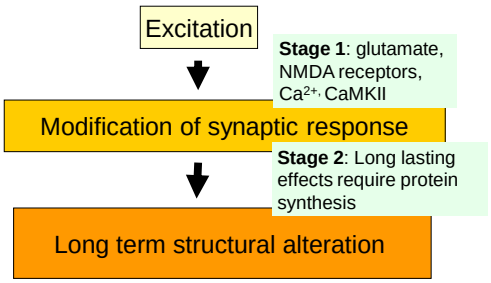
High frequency stimulation leads to Ca^{2+} gating through the NMDA receptor

- CaMKII (calcium and calmodulin dependent kinase) is activated by Ca^{2+}
- CaMKII is autophosphorylated (Thr286) and translocates to the subsynaptic region. Point mutation inhibits LTP and memory formation
- Transient Ca^{2+} signal prolongs kinase activity until dephosphorylated by protein phosphatase

LTP



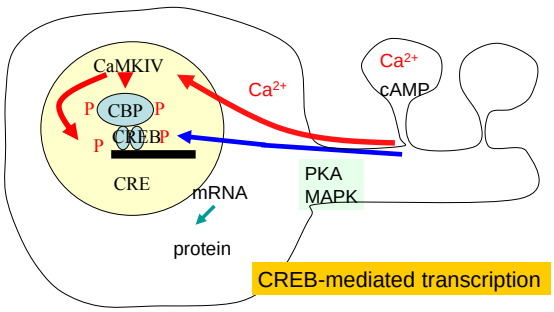
What is the molecular process ?



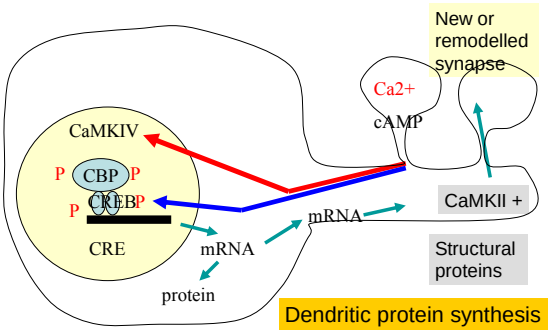
Stage 1: glutamate, NMDA receptors, Ca^{2+}, CaMKII

Stage 2: Long lasting effects require protein synthesis

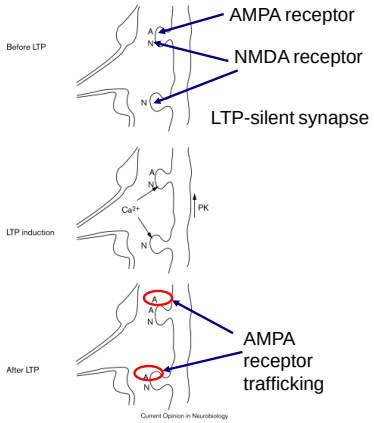
CaMKIV-dominant negative mutants have normal E-LTP but impaired L-LTP and impaired memory consolidation
Nuclear calmodulin inhibition impairs LTP and LTM

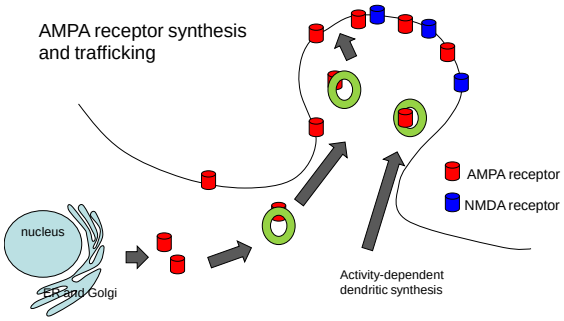


Late phase synaptic plasticity



AMPA receptor Trafficking and the Insertion of AMPA receptors at the synapse is essential for LTP activating "silent synapses"





LTP stimulus

NMDA receptor
$[Ca^{2+}]_i$ increased
CaMKII
PKA

AMPA receptor Phosphorylation

Increased Na^+ conductance

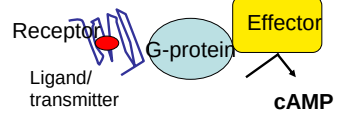
CREB Phosphorlation
▼
transcription

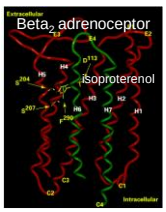
New dendritic protrusions/spines

AMPA receptor Trafficking - synapse

Stage 4: Pathway activation

G-protein coupled receptors





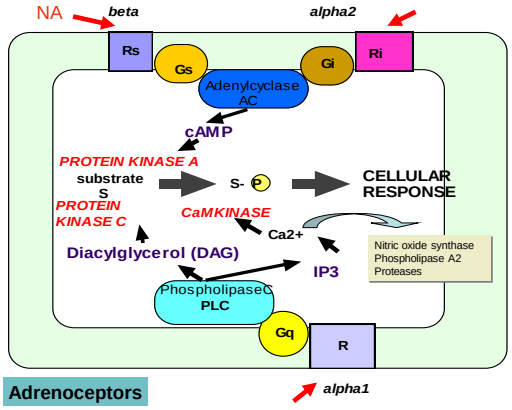
Molecular Cell Biology
Lodish et al (Freeman)

G-protein-coupled receptors mediate the action of many neurotransmitters

Amines: Dopamine, noradrenaline, 5-hydroxy-tryptamine (5-HT), muscarinic cholinergic mACh
Amino acids: $GABA_B$ metabotropic glutamate mGLUR
Neuropeptides: somatostatin, substance P, enkephalin

1. RECEPTOR
   - ~1000 G-protein coupled receptors in the genome (many are 'orphan') - All have 7 alpha helices
   - G-proteins have 3 subunits
     16 alpha subunits define transduction system, 5 beta, 11 gamma subunits
   - Effectors: Adenyl cyclase, Phospholipase C (PLC), cGMP phosphodiesterase, Phopholipase A2, K^+ or Ca^{2+} channels
2. G protein
   G_S G_i G_q G_t
3. EFFECTOR
   enzyme channel
4. Intracellular messenger
   cAMP cGMP Ca^{2+} IP_3

Many GPCR actions are nervous system specific



Adrenoceptors

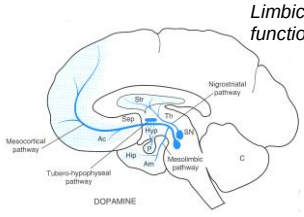
Targets for phosphorylation

- Ion channels * *cell excitability, increases (activation) or decreases (inactivates) open probability*
- Enzymes *affects transmitter availability*
- Receptors *facilitate or desensitise transmitter response*
- Transcription factors (e.g. CREB) *cause long term effects on protein synthesis*

* Direct gating of ion channels by G-proteins also occurs.

Dopamine pathways in the brain

Limbic and motor function



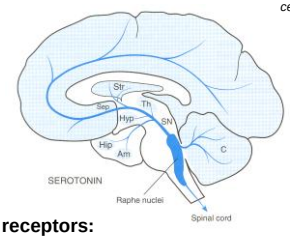
DA receptors:

D_1 and D_5 (D1-type) stimulate cAMP

D_2, D_3 and D_5 (D2-type) inhibit cAMP/ increase IP_3

5-hydroxytryptamine pathways in the brain

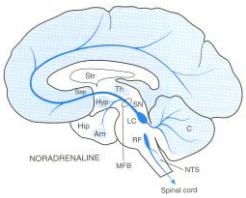
sleep, feeding, anxiety thermoregulation (1A)
cerebral vasoconstriction (1C)
CSF secretion (2C)
emesis, anxiety (3)



5-HT receptors:

$5HT_{1A,\ 1B,\ 1C}$ decrease cAMP
$5HT_{2A,\ 2B,\ 2C}$ increase IP_3/DAG
$5HT_3$ is an ion channel
$5HT_{4,7}$ increase cAMP
$5HT_{5,\ 6}$ CNS effects are less well characterised.

Noradrenergic pathways in the brain



Adrenoceptors:

Beta receptors stimulate cAMP (G_S)
$Alpha_2$ inhibit cAMP ($G_{i/o}$)
$Alpha_1$ increase IP_3 (G_q)
